Abstract: The hydration behavior of calcium aluminate cements in the presence and absence of B₂O₃ was investigated. The hydration rate of these two cements was determined via the exothermic temperature development of cement pastes. The dissolution-precipitation rates of the cement aqueous suspensions were evaluated by means of electrical conductivity. The cement hydration was terminated via vacuum freeze drying, and the resultant hydration products were analyzed by X-ray diffraction. The setting behavior of the mortars was determined by a Vicat apparatus, and the flow values of the castables containing the cements were measured on a vibration table. The results indicate that the presence of B₂O₃ in the cement shortens the induction period of the cements and accelerates the massive precipitation of the hydrates. B₂O₃ contained in the cement promotes the cement hydration rate, reduces the setting time of the mortar and leads to the flow decay of the castable.

Keywords: hydration; calcium aluminate cement; boron oxide; setting time

1 Introduction

Calcium aluminate cements (CACs) are widely used as a binder in refractory castables. The impurities presented in calcium aluminate cement (C ACM) have an impact on the hydration rate and setting behavior of the hydraulic phases¹,³, consequently affecting the placement...
the grain growth of the hydraulic phases and consequently make the hydraulic phases have a higher surface activity\textsuperscript{[1]}. Some studies on high alumina cements showed that the hydration and setting rates of the cements are increased due to the inclusions of TiO\textsubscript{2}, Fe\textsubscript{2}O\textsubscript{3}, MgO and SiO\textsubscript{2} in bauxite of the raw mixes\textsuperscript{[4]}. That is because the minor phases of calcium titanate (CaTiO\textsubscript{3}), ferrite mineral phase, spinel (MgO-Al\textsubscript{2}O\textsubscript{3}) and gehlenite (2CaO-Al\textsubscript{2}O\textsubscript{3}-SiO\textsubscript{2}) phases in the cements serve as crystal nucleus for hydrates, resulting in the decrease of the induction period of the cements\textsuperscript{[2-4]}

Some CAC contains 0.2\%-0.3\% B\textsubscript{2}O\textsubscript{3} because the alumina source in the cement production is alumina dust, which is recovered from production of alumina via the Bayer process and includes 0.5\%-1.0\% boric oxide. It was reported that boric acid retards the setting of CAC bonded castables as an amorphous calcium borate layer precipitates around the cement particles\textsuperscript{[5-6]}. However, it is unclear whether the presence of B\textsubscript{2}O\textsubscript{3} in the cement has an effect on the hydration and setting behaviors of CAC. Little study on this particular aspect has been reported.

This work investigated the hydration behavior of CAC in the presence and absence of B\textsubscript{2}O\textsubscript{3}.

2 Experimental

Commercial calcium aluminate cements (Zhengzhou Aluminates Co., China) with B\textsubscript{2}O\textsubscript{3} (alumina source is from alumina dust) and without B\textsubscript{2}O\textsubscript{3} (alumina source is from the Bayer alumina) were used. Tables 1–3 show the chemical composition, the major phase composition, and the fineness of the cements, respectively.

The exothermic temperature profiles of the cement pastes were measured by a semi-adiabatic method. The water–cement ratio of the cement pastes was 0.36. The temperature caused by the exothermic heat as a function of time was recorded by a type-T thermocouple immersed in the paste and this thermocouple was connected to a data capture system that can record temperature and time. The conductivity of the cement aqueous suspensions with water-cement ratio as 5 at 20 °C and 80% relative humidity (RH) was measured by a model InLab731 conductivity electrode (Mettler Toledo Co., Switzerland). The cement mortars were prepared with a cement-sand ratio of 1 and a water-cement ratio of 0.349. The setting times of cement mortars were determined by a Vicat apparatus based on the Chinese standard GB/T 1346—2011.

The cement pastes above after curing at 20 °C for designed times were frozen at –40 °C for 1.5 h to halt the hydration of the cement pastes. The frozen pastes were immediately dried in a vacuum box under a pressure of 60 Pa at 20 °C. The phase compositions of the dried cement pastes were characterized by a model D8 Focus X-ray diffractometer (XRD) (Bruker Co., Germany). The thermal property was determined by a model STA 449 thermogravimetric analysis (TG) instrument (NETZSCH Co., Germany), using a heating rate of 10 °C/min with nitrogen flow and using α-Al\textsubscript{2}O\textsubscript{3} as a correction standard. The relative weight loss of the cement hydrate phases between the initial and final temperatures was determined via the TG results.

The influence of B\textsubscript{2}O\textsubscript{3} in the cement on the flow decay of the corundum based castables at different time was also investigated. The mixtures were dry-mixed for 1.5 min, followed by 3.5-min wet mixing in a Hobart mixer. Afterwards, the castables were placed into a stainless steel cone with a diameter of 100 mm at the bottom, a diameter of 70 mm at the top and a height of 50 mm. The castables were allowed to flow under vibrating for 15 s at 50 Hz on a vibration table after the cone were lifted up. Then the average of the samples with two perpendicular diameters was measured to calculate the flow value. Furthermore, the changes of the flow value with time were determined at each interval time of 30, 45 and 60 min, respectively.

3 Results and discussion

As shown in Tables 1–3, the chemical composition, major phase composition and fineness of the two cements with and without 0.21% B\textsubscript{2}O\textsubscript{3} are similar. Figure 1 shows the exothermic heat evolution of the cement pastes of CAC with and without B\textsubscript{2}O\textsubscript{3} as a function of time. Clearly, the dormant period of the paste without B\textsubscript{2}O\textsubscript{3} completes at approximately 5 h. However, the dormant period of the paste with B\textsubscript{2}O\textsubscript{3} stops at 2.8 h. Also, the peak of main reaction for hydrate precipitation of the paste without B\textsubscript{2}O\textsubscript{3} after hydration appears for 6.2 h, and the peak of the main reaction for hydration of the paste with B\textsubscript{2}O\textsubscript{3} occurs at 3.8 h. This indicates that the main reaction in the B\textsubscript{2}O\textsubscript{3}-containing paste occurs much earlier than that of the paste without B\textsubscript{2}O\textsubscript{3}. The results above indicate that the presence of B\textsubscript{2}O\textsubscript{3} in the cement accelerates the hydration of CAC at 20 °C.
Figure 2 shows the conductivity of the cements with and without B$_2$O$_3$ at 20 °C as a function of time. It is seen that, initially, the conductivity of the cements with and without B$_2$O$_3$ increases, indicating that the presence of B$_2$O$_3$ in the cement does not affect the dissolution process of the cement. However, the induction period of the B$_2$O$_3$-containing cement is shorter than that of the B$_2$O$_3$-free cement, which is consistent with the shorter dormant period of the former cement than that of the latter one (see Fig. 1). As a result, the sharp decrease in the conductivity of the cement including boric oxide occurs much earlier than that of the cement without boric oxide (see Fig. 2), indicating that the massive precipitation of hydrates starts much earlier in the former cement than in the latter one. The results above indicate that the presence of B$_2$O$_3$ in the cement promotes the oversaturation of Ca$^{2+}$ and Al(OH)$_4^-$ ions in solution with respect to the hydrates and results in the accelerated precipitation of the hydrated calcium aluminate phases. The presence of B$_2$O$_3$ in the cement does not affect the dissolution process of the cements, but accelerates the induction period of the cements and the massive precipitation of the hydrates.

Figure 3 shows the XRD patterns of the hydrated cements with and without B$_2$O$_3$ after hydration at 20 °C for 10 h. It is seen that C$_2$AH$_8$ is the major noticeable hydrate in the cement with and without B$_2$O$_3$ after hydration for 10 h. However, there is more AH$_3$ in the cement with B$_2$O$_3$ than in the cement without B$_2$O$_3$ after the hydration. As AH$_3$ is the by-product of C$_2$AH$_6$ transformed from metastable hydrates such as CAH$_{10}$[2,7-8] the more amount of AH$_3$ in the B$_2$O$_3$-containing cement means that B$_2$O$_3$ in the cement should generate a higher content of metastable hydrates such as CAH$_{10}$. As a result, the presence of B$_2$O$_3$ in the cement accelerates the hydration of the cement and the formation of hydrates. With respect to the exothermic temperature and conductivity of the cement pastes, the promoted formation of AH$_3$ in the cement with B$_2$O$_3$ after hydration for 10 h (see Fig. 3) is compatible with the shorter dormant period of the B$_2$O$_3$-containing cement (see Figs. 1 and 2). Nevertheless, the mechanism of the presence of B$_2$O$_3$ in the cement facilitated the hydration of CAC needs to be further investigated.

Figure 4 shows the TG diagram of the cements with and without B$_2$O$_3$ after hydration at 20 °C for 10 h. The different dehydration stages at various temperatures are attributed to removal of surface bonded water, dehydration of aluminium hydroxide gel, dehydration of CAH$_{10}$ to C$_2$AH$_6$, dehydration of C$_2$AH$_6$ to C$_3$AH$_6$, and dehydration of C$_3$AH$_6$ to anhydrous CA, respectively.[9] Table 4 shows the weight losses at different temperatures caused by different hydrates. It is seen that the weight loss of the cement paste without B$_2$O$_3$ at 70–90 °C is 0.63%, while the weight loss of paste with B$_2$O$_3$ is 1.30%. The greater weight loss could be ascribed to the more amount of AH$_3$ in the paste with B$_2$O$_3$[10] which is in agreement with the more AH$_3$ in the cement with B$_2$O$_3$ (see Fig. 3). Table 4 also exhibits that the mass loss of 1.96% caused due to the decomposition of CAH$_{10}$ in the paste with B$_2$O$_3$ is greater than that in the paste without B$_2$O$_3$ (i.e., 1.65%). Moreover, the temperature ranges for dehydration of C$_2$AH$_6$, AH$_3$ and C$_3$AH$_6$ are obviously overlapped.[10-11] It is thus difficult to differentiate the weight losses of the cement pastes caused by C$_2$AH$_6$,
AH₃ and C₃AH₆. However, the total mass loss of the paste with B₂O₃ at 160–350 ℃ resulting from dehydration of C₂AH₈, AH₃ and C₃AH₆ is 7.34%, while that is 4.27% in the paste without B₂O₃, also indicating more hydrates in hydrated cement with B₂O₃. The weight losses between the hydrated cements with and without B₂O₃ demonstrates that B₂O₃ in cement promotes the cement hydration process, which is consistent with the results from the XRD results (see Fig. 3).

Figure 5 shows the initial and final setting time of the mortars including the cements with and without B₂O₃ at 20 ℃. Clearly, the mortar containing the cement without B₂O₃ has an initial setting time of 133 min and a final setting time of 158 min. However, the initial setting time and the final setting time of the mortar including the cement with B₂O₃ are 55 and 90 min, respectively. This indicates that the hydration of the cements is accelerated in the presence of B₂O₃ in the cement.

Figure 6 shows the time-dependent decay of the flow values of corundum-based castables including the cements with and without B₂O₃ at 20 ℃. Clearly, the presence of B₂O₃ in the cement does not affect the flow values of the castable within the initial 30 min. However, the flow value decay of the castable is more pronounced with the cement with B₂O₃, due to the accelerated induction period and faster precipitation behavior of the cement containing B₂O₃. These results confirm that the hydration of the cements in castables is accelerated in the presence of B₂O₃ in the cement.

### 4 Conclusions

The presence of B₂O₃ in the cement did not affect the dissolution process of the cements, but shortened the induction period of the cements and accelerated the massive precipitation of the hydrates. The accelerated hydration caused in the presence of B₂O₃ in the cement occurred due to the greater amount of hydrates in the hydrated cement with B₂O₃. Consequently, the initial setting time and the final setting time of the mortar including the cement with B₂O₃ were reduced and the flow value of the castable containing the cement with B₂O₃ decayed faster than that of the castable without B₂O₃.
